Abstract

In this study, the erosion properties of four sediments related to the Canaveral Ocean Dredged Material Disposal Site have been determined as a function of density, consolidation, and shear stress by means of a high shear stress sediment erosion flume at Sandia National Laboratories. Additional analysis was completed for each sediment to determine mineralogy, particle size, and organic content. This was done to support numerical modeling efforts, aid in effective management, and minimize environmental impact. The motivation for this work is based on concerns of dredged material transporting beyond the designated site and estimates of site capacity.

1. Introduction

The U.S. Environmental Protection Agency (EPA) has the responsibility under Section 102 of the Marine Protection Research and Sanctuaries Act (MPRSA) for the management and monitoring of Ocean Dredged Material Disposal Sites (ODMDS). The Canaveral ODMDS was designated by EPA in 1990 for disposal of dredged material from the U.S. Navy Trident Basin and Entrance Channel, the Port of Canaveral facilities, and the Corps of Engineers Civil Works Projects at Canaveral. Concurrent with the site designation in 1990 a Site Management and Monitoring Plan (SMMP) was developed. This plan is currently in the process of revision. A main component of site monitoring is the determination of the short-term and long-term fate of materials disposed in the marine environment. Concern has been raised regarding the magnitude and extent of disposed dredged material dispersal outside of the ODMDS boundaries and the potential for disposed dredged material impacting potential future offshore sand sources for beach renourishment. Additionally, a quantitative analysis is needed to provide an estimate of the long term capacity of the disposal site. Close to 1 million cubic yards of material are disposed of at the Canaveral ODMDS every year. A significant portion of this material comes from the entrance channel where the sediments have been classified as stiff clays and silts, with horizons of very fine silty sand, shell fragments, and organics.

Numerous studies prior and subsequent to site designation have indicated that the ODMDS is a dispersive site for fine grained material and as a result, dredged material may extend well beyond the designated site boundaries. However, adequate site specific information is not available to allow for a conclusive and quantitative statement regarding sediment transport from the ODMDS. In order to address this issue, this work is intended

to collect site specific information regarding the erodibility of dredged material disposed at the Canaveral ODMDS. Parameters calculated from this work can be used in existing numerical models to provide quantitative estimates of the sediment transport occurring within and near the ODMDS. This in turn can be used to effectively manage the Canaveral ODMDS to minimize environmental impact.

In this study, the erosion rates of four reconstituted sediments, two from the Canaveral ODMDS and two from the Canaveral Harbor, have been determined as a function of density and shear stress by means of the High Shear Stress Sediment Erosion Flume at Sandia National Laboratories. For all cores, bulk density was determined as a function of depth and consolidation time. Sediment cores were eroded to determine erosion rates as a function of density and shear stress. In addition, each sediment was analyzed for particle size, mineralogy, and organic content.

In the following section, descriptions of the high shear stress sediment erosion flume and experimental procedures are given. The results of laboratory studies for the reconstituted sediments are presented in section 3. The fourth section discusses the results for the consolidation, bulk parameter, and erosion properties, and the summary and concluding remarks are given in the final section.

2. Experimental Procedures

The information in this section is partially based on the articles by Jepsen, et al. (1997a), and Roberts, et al. (1998).

2.1 Description of the High Shear Stress Sediment Erosion Flume

A schematic of the High Shear Stress Sediment Erosion Flume is shown in Figure 1 and is essentially a straight flume, which has a test section with an open bottom through which a rectangular cross-section coring tube containing sediment can be inserted. The main components of the flume are the coring tube; the test section; an inlet section for uniform, fully developed, turbulent flow; a flow exit section; a water storage tank; and a pump to force water through the system. The coring tube, test section, inlet section, and exit section are made of clear acrylic or polycarbonate so that the sediment-water interactions can be observed. The coring tube has a rectangular cross-section, 10 cm by 15 cm, and can be up to 1 m in length.

Water is pumped through the system from a 120 gallon storage tank, through a 5 cm diameter pipe, and then through a flow converter into the rectangular duct shown. This duct is 5 cm in height, 10 cm in width, and 200 cm in length; it connects to the test section which has the same cross-sectional area and is 15 cm long. The flow converter changes the shape of the cross-section from circular to the rectangular duct. The flow is regulated by a three-way valve so that part of the flow goes into the duct while the remainder returns to the tank. Also, there is a small valve in the duct (not shown)

immediately downstream from the test section which is opened at higher flow rates to keep the pressure in the duct and over the test section at atmospheric conditions.

At the start of each test, the coring tube is filled with reconstructed sediments. The procedure for preparing the reconstructed sediments in the laboratory will be described in Section 2.3. The coring tube and the sediment it contains are then inserted into the bottom of the test section. An operator moves the sediment upward using a piston which is inside the coring tube and is connected to a mechanical jack and then driven by a variable-speed controller. By this means, the sediments can be raised and made level with the bottom of the test section. The speed of the jack movement can be controlled at a variable rate in measurable increments as small as 0.25 mm.

Water is forced through the duct and the test section over the surface of the sediments. The shear produced by this flow causes the sediments to erode. As the sediments in the core erode, the core is continually moved upwards by the operator so that the sediment-water interface remains level with the bottom of the test and inlet sections. The erosion rate is recorded as the upward movement of the sediments in the coring tube over time.

2.2 Hydrodynamics

For the flow rates of interest, it can be shown that fully developed turbulent flow exists in the test section. Turbulent flow through pipes has been studied extensively, and empirical functions have been developed which relate the mean flow rate to the wall shear stress. In general, flow in circular cross-section pipes has been investigated. However, the relations developed for flow through circular pipes can be extended to non-

circular cross-sections by means of a shape factor. An implicit formula relating the wall shear stress to the mean flow in a pipe of arbitrary cross-section can be obtained from Prandtl's Universal Law of Friction (Schlichting, 1979). For a pipe with a smooth surface, this formula is

$$\frac{1}{\sqrt{\lambda}} = 2.0 \log \left[\frac{UD\sqrt{\lambda}}{\nu} \right] - 0.8 \quad (2.1)$$

where U is the mean flow speed, ν is the kinematic viscosity, λ is the friction factor, and D is the hydraulic diameter defined as the ratio of four times the cross-sectional area to the wetted perimeter. For a pipe with a rectangular cross-section, or duct, the hydraulic diameter is

$$D = 2hw/(h + w) \quad (2.2)$$

where w is the duct width and h is the duct height. The friction factor is defined by

$$\lambda = \frac{8\tau}{\rho U^2} \quad (2.3)$$

where ρ is the density of water and τ is the wall shear stress. Inserting Eqs. (2.2) and (2.3) into Eq. (2.1) then gives the wall shear stress τ as an implicit function of the mean flow speed U . For the above equations, h is 5 cm, w is 10.5 cm, ρ is 1 g/cm³, and ν is 0.01 cm²/s. Table 1 shows mean velocities, U , and their corresponding shear stresses.

For shear stresses in the range of 0.1 to 10 N/m², the Reynolds numbers, UD/ν , are on the order of 10^4 to 10^5 . These values for Reynolds numbers are sufficient for turbulent flow to exist for the stresses of interest in this study. For flow in a circular pipe, turbulent flow theory suggests that the transition from laminar to turbulent flow occurs within 25 to 40 diameters from the entrance to the pipe. Since the hydraulic diameter of the duct pipe is 6.8 cm, this suggests an entry length of approximately 170 to 270 cm. The length of the duct leading to the test section is 180 cm and is preceded by a 20 cm flow converter and several meters of inlet pipe. These arguments along with direct observations indicate that the flow is fully turbulent in the test section.

2.3 Core Preparation

To gain insight on how sediment consolidation parameters (namely bulk density or water content of the sediment) affect erosion rates, reconstituted sediments were prepared in the laboratory. To obtain different bulk densities, sediment cores were prepared as follows. Approximately 20 gallons of wet sediments were placed in 35 gallon cylindrical tanks and mixed until the sediment-water mixture was homogeneous. The sediment mixtures were then poured into at least five 30 cm coring tubes. These cores were allowed to consolidate for 2, 10, 30, 60, and 90 days.

2.4 Measurements of Sediment Erosion Rates

The procedure for measuring the erosion rates of the sediments as a function of shear stress and depth was as follows. The sediment cores were prepared as described above and then moved upward into the test section until the sediment surface was even

with the bottom of the test section. A measurement was made of the depth to the bottom of the sediment in the core. The flume was then run at a specific flow rate corresponding to a particular shear stress. Erosion rates were obtained by measuring the remaining core length at different time intervals, taking the difference between each successive measurement, and dividing by the time interval.

In order to measure erosion rates at several different shear stresses using only one core, the following procedure was generally used. Starting at a low shear stress, the flume was run sequentially at higher shear stresses with each succeeding shear stress being twice the previous one. Generally about three shear stresses were run sequentially. Each shear stress was run until at least 5 mm but no more than 4 cm were eroded. Also, each shear stress was run for a minimum of 20 seconds and a maximum of 15 minutes. This defines the minimum and maximum erosion rates measured by the high shear stress sediment erosion flume to be about 1.0×10^{-4} and 0.1 cm/s respectively. The time interval was recorded for each run with a stop watch. The flow was then increased to the next shear stress, and so on until the highest shear stress was run. This cycle was repeated until all of the sediment had eroded from the core. If after three cycles a particular shear stress showed a rate of erosion less than 10^{-4} cm/s, it was dropped from the cycle; if after many cycles the erosion rates decreased significantly, a higher shear stress was included in the cycle.

2.5 Measurements of Critical Shear Stress for Erosion

A critical shear stress can be quantitatively defined as the shear stress at which a very small, but accurately measurable, rate of erosion occurs. In the present study, this

rate of erosion was chosen to be 10^{-4} cm/s; this represents 1 mm of erosion in approximately 15 minutes.

2.6 Measurements of Sediment Bulk Properties

For the analysis of the sediment bulk properties duplicate cores were made that were prepared the same as the erosion cores. The core sleeves of these analysis cores were made from 7.6 cm inner diameter thin acrylic tubes of the same length as the rectangular cores.

To determine the bulk density of the sediments at a particular depth and consolidation time, the sediment analysis cores were frozen, sliced into 2.5 cm sections, and then weighed (wet weight). They were then dried in the oven at approximately 75°C for 2 days and weighed again (dry weight). The water content W is then given by

$$W = \left(\frac{m_w - m_d}{m_w} \right) \quad (2.4)$$

where m_w and m_d are the wet and dry weights respectively. A volume of sediment, V , consists of both solid particles and water, and can be written as

$$V = V_s + V_w \quad (2.5)$$

where V_s is the volume of solid particles and V_w is the volume of water. If the sediment particles and water have densities ρ_s and ρ_w respectively, the water content of the sediment can be written as

$$W = \frac{\rho_w V_w}{\rho V} \quad (2.6)$$

where ρ is the bulk density of the sediments. A mass balance of the volume of sediment gives

$$\rho V = \rho_s V_s + \rho_w V_w \quad (2.7)$$

By combining Eqs. (2.5), (2.6), and (2.7), an explicit expression can be determined for the bulk density of the sediment, ρ , as a function of the water content, W , and the densities of the sediment particles and water. This equation is

$$\rho = \frac{\rho_s \rho_w}{\rho_w + (\rho_s - \rho_w)W} \quad (2.8)$$

For the purpose of these calculations, it has been assumed that $\rho_s = 2.6 \text{ gm/cm}^3$ and $\rho_w = 1.0 \text{ gm/cm}^3$.

Particle sizes and particle size distributions were determined by use of a Malvern Mastersizer S particle sizing package for particle diameters between 0.05 and 900 μm .

All sediment samples had particle sizes less than 900 μm . Approximately 5 to 10 grams

of sediment were placed in a beaker containing about 500 mL of water and mixed by means of a magnetic stir bar/plate combination. Approximately 1 mL of this solution was then inserted into the sizers sampling system and further disaggregated as it is recirculated through the sampling system by means of a centrifugal pump. The sample was allowed to disaggregate for five minutes on the stir plate and an additional five minutes in the recirculating pump sampling system before analysis by the sizer. To ensure complete disaggregation and sample uniformity the sediment samples were analyzed multiple times and repeated in triplicate. From these measurements, the distribution of grain sizes and mean grain sizes as a function of depth were obtained.

The dry sediment was crushed into powder and then weighed. Approximately 5 mL of 10% hydrochloric acid was added to every 1 gram of dry sediment (Tye et al. 1996). The sample was again dried in the oven at 75°C, and analyzed in an UIC, Inc. Model CM5014 CO₂ Coulometer to determine the total organic carbon content of the sediment.

The mineralogies of the sediments were determined by means of X-ray powder diffraction using a Bruker, AXS Model D8 Advance X-ray Diffractometer. Samples were crushed to a size of about 10 µm before being measured by X-ray diffraction.

3. Results for Laboratory Consolidation and Erosion Tests

Tests were done to determine erosion properties for four sediments retrieved from the Canaveral ODMDS and Harbor with respect to consolidation and bulk density. The sites are identified as CDS-1, CDS-2, CHB-2, and CH-EC-S-1. CDS-1 and CDS-2 are from the ODMDS. CH-B-2 is from the West Turning Basin of the Canaveral Harbor and CH-EC-S-1 was a composite of samples collected from a disposal barge with sediments dredged from the Canaveral Harbor Entrance Channel.

3.1 Bulk Properties

Particle size, bulk density, organic content, and mineralogy of each of the four composite sediment mixtures were measured. The size distributions for each composite are shown in Figure 2. The mean particle size was 52.2, 92.2, 27.1, and 23.3 μm for the CDS-1, CDS-2, CH-EC-S-1, and CHB-2 sediments respectively. The organic content for the composite mixture was 3.21 % for CDS-1, 2.23 % for CDS-2, 4.37% for CH-EC-S-1, and 3.57% for CHB-2. The mineralogy of each composite and a summary of all sediment properties are shown in Table 2. Particle size, organic content, and mineralogy were constant with depth for each composite core. Bulk density was the only parameter that was a variable in each core.

Bulk density was determined as a function of depth for 30 cm core lengths. Consolidation times were between 2 and 90 days for each core. Densities were determined by measuring the water content of each core in 2.5 cm increments. Sediment bulk densities are shown in Figure 3a-d for CDS-1, CDS-2, CH-EC-S-1, and CHB-2

sediments respectively. For all cores, the bulk density generally increases with depth and consolidation time.

3.2 Erosion Rates

Erosion rates as a function of shear stress and depth were obtained for all sediments at consolidation times of 2, 10 and 60 days. Erosion rates were measured for shear stresses of 0.5, 1.0, 2.0, and 4.0 N/m². The erosion rates for the lower shear stress of 0.5 N/m² could only be reasonably measured for the upper portion of the cores and for short consolidation times (i.e., low densities). This is because erosion either did not occur or was so slow that it would have taken hours to days to erode a measurable amount of sediment. Likewise, the 4.0 N/m² shear could not be tested at all depths because it eroded low bulk density areas too fast for the operator to accurately measure erosion rates.

All of the data for erosion rates as a function of bulk density for shear stresses of 0.5, 1.0, 2.0, and 4.0 N/m² are shown for each sediment in Figures 4a-d. Erosion rates vs. depth for each sediment and consolidation time is shown in Figures 5a-c for CDS-1, 6a-c for CDS-2, 7a-c for CH-EC-S-1, and 8a-c for CHB-2. A large decrease in erosion rate as the bulk density increases can be seen at all shear stresses. A smaller decrease in erosion rates was seen as a function of depth for each consolidation time. In general, the data can be approximated by an equation of the form

$$E = A\tau^n\rho^m \quad (3.1)$$

where E is the erosion rate (cm/s), τ is the shear stress (N/m^2), ρ is the bulk density (g/cm^3), and n , m , and A are constants. The constants are shown in Table 3 for each composite sediment. For each shear stress, the erosion rate as a function of bulk density is shown as a straight line which demonstrates that the above equation represents the data quite well and also that the erosion rate is a unique function of shear stress and bulk density. This relationship (with different constants) has been shown successfully to describe many other natural and synthetic sediments (Jepsen et al, 1997a, 1997b and 1998, and Roberts et al, 1998).

There were fewer data obtained for the CH-EC-S-1 and CHB-2 sediments compared to the CDS-1 and CDS-2 sediments. The CH-EC-S-1 and CHB-2 sediments were much finer in particle size and more cohesive than the other sediments and generally eroded as 1 to 2 cm aggregates rather than as individual particles or smaller millimeter sized aggregates. This erosion behavior required larger depth intervals (~3 to 4 cm) to obtain accurate erosion rate data. In addition, at shear stresses of 2.0 N/m^2 and consolidation times greater than 10 days, the sediments would occasionally develop a horizontal fracture at depths up to 5 cm in which an entire section of the sediment would lift out of the core and into the test section. This failure mode from the lift forces on the surface of the cohesive sediments is difficult to quantify and is not included in the plots showing the erosion rate as a function of density. Table 4 summarizes the depth consolidation time, and depth at which these large failures occurred.

3.3 Critical Shear Stress

The critical shear stress can also be determined as a function of bulk density. From Eq. (3.1), the shear stress, τ , can be defined as the critical shear stress, τ_{cr} , by setting the erosion rate, E , to 10^{-4} cm/s. Solving for τ_{cr} as a function of bulk density gives

$$\tau_{cr} = \left[\frac{E}{A} \right]^{\frac{1}{n}} \rho^{-\frac{m}{n}} \quad (3.2)$$

By substituting 10^{-4} cm/s for the erosion rate and the constants n , m , and A for each sediment into the above equation, one obtains a general relation for the critical shear stress. Substituting the constants listed in Table 3 for each sediment shows that the critical shear stress increases rapidly with small increases of bulk density.

Since tests were done for most of the shear stresses at erosion rates down to 10^{-4} cm/s, Eq. (3.2) is well supported by experimental data. However, Eq. (3.2) can also approximate the data for erosion rates less than the defined 10^{-4} cm/s erosion rate for the critical shear stress. Although erosion rates less than 10^{-4} cm/s may be difficult to measure accurately, the curves plotted in Figures 4a-d that are described by Eq. (3.1) could be extrapolated to lower erosion rates. This would allow the critical shear stress to be predicted for an erosion rate of 10^{-5} cm/s as well. For example, Figures 9a-d show the critical shear stress (calculated for erosion rates of 10^{-4} and 10^{-5} cm/s) as a function of bulk density as determined from Eq. (3.2) each composite.

4. Discussion of Results

4.1 Consolidation Properties

The consolidation of all sediments generally show an increase in density with time and depth. The sediments that consolidated slowly and had lower densities (CH-EC-S-1, CHB-2, and CDS-1) showed more density variation with time rather than depth. The sediments from CDS-2 consolidated quickly and reached steady state between 30 and 60 days with the majority of consolidation occurring between 2 and 10 days. The other three sediments reached a quasi-steady state at about 60 to 90 days. In addition, the CDS-2 sediments were significantly more dense than the other sediments. This was probably due to the larger grain size of CDS-2 and its ability to expel the pore water quickly. Since the sediments that consolidated to a lower density were fine-grained and cohesive, they are less permeable and the pore water has difficulty escaping to the surface.

4.2 Bulk Properties

The bulk properties showed that all the sediments were similar in mineralogy. However, the CH-EC-S-1 and CHB-2 sediments were also somewhat similar in particle size, organic content, and density. CDS-1 and CDS-2 contained a significant amount of sand sized material mixed with fine-grained silts and clay-sized material. However, the majority of CDS-2 was sandy and CDS-1 was about half sand and half silt.

It should be noted that although all of the sediments had a significant size fraction less than 10 μm , no clays were evident in any of the sediments. Despite the absence of clays, the two sediments with the smallest particle size (CH-EC-S-1 and CHB-2) were very cohesive. The lack of clays does not necessarily preclude sediments from behaving

in a cohesive manner. Roberts et al. 1998 demonstrated that pure quartz behaves in a cohesive manner at sizes of 5 to 125 μm .

Finally, there is a clear relationship between particle size, organic content, and density. The sediment with the lowest density, CH-EC-S-1 also had the smallest particle size and highest organic content while the sediment with the highest density CDS-2 had the largest particle size and lowest organic content. This relationship was true for all four sediments with respect to density, particle size and organic content.

4.3 Erosion Properties

There was a strong dependence on bulk density for the erosion rates of all the sediments. The dependence on bulk density was greatest for CHB-2 and CH-EC-S-1. This can be demonstrated by the magnitude of the slope of m for ρ from Eq. (3.1). These two sediments were also fine-grained and the dependence on density can be used as a qualitative measure of their cohesiveness. The dependence on density for the CDS-1 and CDS-2 sediments was approximately a factor of two less than that for the finer-grained sediments.

Erosion rates can also be compared to consolidation time. The sediments from CDS-1 and CDS-2 were the most erosion resistant for short times (Figures 3a,b and Figures 4a,b). However, at 60 days, the sediments from CH-EC-S-1 and CHB-2 had similar erosion rates at the same shear stresses as CDS-1 and CDS-2. Extrapolating the data to higher densities for each sediment shows that CH-EC-S-1 and CHB-2 would become more difficult to erode than the larger-grained sediments at the same density. However, these sediments do not appear to exist at higher densities since they seem to be

at a steady state in 60 days (Figures 3a-d). This demonstrates that more cohesive sediments may be less erosion resistant at short and perhaps all consolidation times because of the inability to expel the pore water.

4.4 Comparison with Other Natural Sediments

From Figure 10 it can be seen that the density range and erosion properties are unique for each natural sediment. In general, sediments containing more sand or coarse-grained material have higher density ranges and less dependence on bulk density while the fine-grained, silty sediments have lower density ranges and greater dependence on density. The CDS-1 and CDS-2 sediments were qualitatively similar to other sediments found in near shore areas or harbors. These types of sediments generally contain some fraction of sand as did CDS-1 and CDS-2. CDS-1 was similar to sites H06 and Ward1B from the New York Harbor dumpsite. CDS-2 was similar in density range to A30NE from the New York Harbor dumpsite, but the relationship between density and erosion rates was quite different as shown by the difference in slope between these two sediments.

The CHB-2 and CH-EC-S-1 sediments were more similar to the fine-grained sediments found in river systems such as the Grand River, MI or the Fox River, WI. Their density range was lower than any sediment previously tested. However, they did have a similar relationship between erosion rate and density as shown by the steep slope which is also present with the fine-grained riverine sediments.

5.0 Summary and Concluding Remarks

By means of the experiments described here, the effects of sediment bulk density on erosion rates were measured for four composite sediments from the Canaveral ODMDS. From these experiments, the following was determined. (1) The bulk density of the sediments generally increases with depth and time. (2) For each sediment and shear stress, the erosion rate is a unique function of bulk density and decreases as the bulk density increases. (3) For each sediment, the erosion rate can be approximated as $E = A\tau^n \rho^m$ (Eq. 3.1) where, A, n, and m are sediment specific, experimentally determined constants. The relationship between erosion rate, bulk density, and shear stress also allows one to predict erosion at any depth and consolidation time for the entire range of density for each sediment using the data plotted on Figures 3a-d and Eq.(3.1). Overall, the CDS-2 sediment was the most erosion resistant at all consolidation times, whereas CH-EC-S-1 and CHB-2 were the least erosion resistant.

In addition, each sediment was analyzed for bulk density, particle size, mineralogy, and organic content. The mineralogy of each sediment was similar for all sediments tested. The particle size and bulk density was alike for CH-EC-S-1 and CHB-2, and dissimilar for the other two sediments. Finally, the organic content ranged from 2 to 4% for all sediments.

It should be emphasized that the results reported here determine the effects of bulk density and consolidation time on erosion for each individual sediment. These and other tests have indicated that there is at least a qualitative relationship between other bulk properties such as mineralogy, particle size and size distribution, and organic content. Since the measurements of sediment bulk properties are standard and can be

determined relatively easily, it would be useful if sediment erosion rates could be predicted from knowledge of the sediment bulk properties. At present, this cannot be done. However, from experiments such as these, it is hoped that this will soon be accomplished.

Table 1. Shear Stresses and Corresponding Mean Velocities

Shear Stress (N/m ²)	Mean Velocity (cm/s)
0.1	16.3
0.5	40.9
1	60.5
2	89.4
4	131.8
6	165.2
8	194.0
10	219.6

Table 2. Summary of all Sediment Bulk Properties

Sediment Name	Bulk Density Range (g/cm ³)	Mean Particle Size (μm)	Mean Organic Content (% by mass)	Mineralogy (Minerals listed in descending amount)
CDS-1	1.33-1.44	52.2	3.21	Quartz, Muscovite, Albite, Microcline
CDS-2	1.55-1.65	92.2	2.23	Quartz, Muscovite, Albite, Microcline
CH-EC-S-1	1.20-1.25	23.3	4.37	Quartz, Albite, Microcline, Muscovite
CHB-2	1.21-1.27	27.1	3.57	Quartz, Microcline, Muscovite, Albite

Table 3. Constants for Equation 3.1 for the four composite sediments

Sediment	n	m	A
CDS-1	2.32	-43.9	1055
CDS-2	2.71	-66.8	3.35×10^{10}
CH-EC-S-1	2.73	-107.1	1.33×10^6
CHB-2	2.51	-105.2	4.85×10^6

Table 4. Summary of Sediment Failure Modes during Erosion Tests

Identity	Consolidation Time (days)	Depth (cm) Where Failure Occurred
CHB-2	10	7.5-9.5
CHB-2	10	11.5-13.0
CHB-2	60	5.5-10.0
CHB-2	60	11.5-15.5
CH-EC-S-1	2	8.5-11.0
CH-EC-S-1	10	11.0-14.0
CH-EC-S-1	10	17.0-19.0
CH-EC-S-1	60	7.5-12.5
